ABSTRACT

Background: The radiological techniques namely chest radiography (chest X-ray) and computerized tomography (CT) scan play a major role not only in the early detection and diagnosis, especially for false negative Real Time-Polymerase Reaction (RT-PCR) tests and in admission criteria, monitoring the clinical course and the disease severity.

Objective: The study aimed to describe the radiological features of chest X-ray and CT scan in coronavirus diseases 2019 (COVID-19) patients, Hodeidah, Yemen.

Methodology: A descriptive study (a case series) included 49 patients with COVID-19, confirmed by RT-PCR who were admitted in isolation department of COVID-19, Center of Tropical Medicine and Infectious Diseases (CTMID), AL Thawra Public Hospital Authority, Hodeidah, Yemen who
underwent serial chest X-ray and CT scan, from 1st June to 31st December 2021. The cases reports of patients from 3 to 80 years old. Image features and their distribution were analyzed and the COVID-19 Reporting and Data System (CO-RADS) for level of suspicion of COVID-19 infection was applied.

**Results:** The results showed that 21 /49 patients (42.86 %) of CO-RAD 4 and 28 /49 patients (57.14 %) of CO-RAD 5. The most patterns were 42/49 patients (85.71 %) of ground glass opacification (GGO), 40/49 patients (81.63%) of bilateral involvement, 41/49 patients (83.67 %) of multi-lobar involvement, 37/49 patients (75.51 %) of peripheral distribution, 15/49 patients (30.61 %) of consolidation pattern and 3/49 patients (6.12%) of crazy paving pattern. On the other hand, in the youngest patients less than 50 year, 79 % had GGO, and 21 % had lung consolidations, while in the patients over 50 year, GGO were presented in 56 % and consolidations in 44 %. In addition, the lung involvement range of patients was from 40 to 95 % and the median was 60 %. The lung involvement was represented in the patients more than 50 year as 60 – 95 % while in the patients less than 50 years was represented as 40 – 55 %. The lung involvement of death patients was 85 to 95 % of non-chronic diseases and 60 to 70 % of comorbidity and coinfection.

**Conclusion:** The study concluded that different radiological patterns and features were reported in elderly patients with COVID-19 infection associated with risk factors (comorbidity and coinfection). The radiological techniques have good predictive values on severity and mortality. Also can support the clinicians staff in early detection, early triage, criteria admission, and effective management of COVID-19 infection.

1. **INTRODUCTION**

Radiological techniques have an important role to play in the diagnosis and assessment of the coronavirus disease 2019 (COVID-19). Radiological techniques namely radiography (X-ray) and computed tomography (CT) scan are primarily to assess the severity and/or impact of COVID-19 on patients who have tested positive for the virus and who are experiencing severe and/or problematic symptoms [1].

World Health Organization (WHO) published rapid advice guide examines the evidence and makes recommendations for the use of chest imaging in acute care of adult patients with suspected, probable or confirmed COVID-19. Imaging modalities considered are X-ray and CT scan. This guide addresses the care pathway from presentation of the patient to a health facility to patient recovery. It considers different levels of disease severity, from asymptomatic individuals to critically ill patients [2].

According to a Fleischner Society consensus statement published on 7 April 2020, imaging is not indicated in patients with suspected COVID-19 and mild clinical features unless they are at risk for disease progression, imaging is indicated in a patient with COVID-19 and worsening respiratory status, in a resource-constrained environment, imaging is indicated for medical triage of patients with suspected COVID-19 who present with moderate-severe clinical features and a high pretest probability of disease [3-5].

The study aimed to describe the radiological patterns and features of chest X-ray and CT scan of COVID-19 patients in Hodeidah, Yemen.

2. **METHODOLOGY**

2.1 **Study Area**

Hodeidah Governorate is located on the western, flat and narrow coastal plain between the foothills of the highlands and the red sea. Hodeidah is the fourth largest Governorate in Yemen in the term of population which reaches to about (2157552). The area is 13500 km2 involves 26 Districts, and a lot of islands in the red sea. The weather is typically hot and humid and the temperatures sometimes exceeding 38 to 40° C. During the rest of the year temperature range between 27-35 °C. This region is known to have high conflict area since the 26th of March 2015. Hodeidah, Yemen also is considered as an endemic zone for numerous infectious diseases namely dengue and malaria [6-9].

2.2 **Study Design**

This work was designed in a descriptive study (a series case). The patients who were admitted in the COVID-19 Isolation Department, Center of

2.3 Chest X-ray and CT Scan Protocol

Chest X-ray was performed in the antero-posterior projection. All images were stored in a picture archiving and communication system (AGFA Computed Radiography). Patients with CT scan were received a non-contrast chest CT scan (unless iodinated contrast medium is indicated), with reconstructions of the volume at 0.625 mm to 1.5 mm slice thickness (gapless).

If iodinated contrast medium is indicated, such as in CT pulmonary angiogram (CTPA), a non-contrast scan should be considered prior to contrast administration, as contrast may impact the interpretation of results. Multi-detector CT (MDCT) machine with High-resolution CT (HRCT) protocol was applied. The Dutch Association for Radiology (NVvR) proposed a CT scan scoring system for COVID-19. They called it COVID-19 Reporting and Data System (CO-RADS) to ensure CT scan reporting is uniform and replicable [10-12].

3. RESULTS

3.1 Radiological Finding According to Age and Sex

The patients were classified into 2 groups according to their age, patients younger than 50 year and patients older than 50 year. In the youngest group of patients, 79% had ground glass opacification (GGO), and 21% had lung consolidations (Fig 3 and 4). While in the group of patients over 50 year, GGO were present in 56% and consolidations in 44% (Fig. 5 and 6). Males were significantly overrepresented in this group compared with females ($X^2 = 19.61; p = 0.0001$) (Table 2).

3.2 Radiological Finding According to Severity

Lung involvement of COVID-19 patients was diagnosed in admitted patients using CT scan. The lung involvement was represented in the patients more than 50 year as 60 – 95% while in the patients less than 50 year was represented as 40 – 55%. The lung involvement range of COVID-19 patients was from 40 to 95% and the median was 60%. The relationship between the lung involvement (%) and mortality was reported where the lung involvement in death patients was 85 to 95% of non-chronic diseases and 60 to 70% of comorbidity and coinfection (Table 3).

3.3 Radiological Patterns

CO-RAD levels of suspicion of COVID-19 infection was summarized in Table 4 and Figure 1. 21/49 patients (42.86%) of CO-RAD 4 and 28/49 patients (57.14%) of CO-RAD 5. On the other hand, the radiological features were reported and the most patterns were 42/49 patients (85.71%) of GGO, 40/49 patients (81.63%) of bilateral involvement, 41/49 patients (83.67%) of multi-lobar involvement, and 37/49 patients (75.51%) of peripheral distribution. The least patterns were 15/49 patients (30.61%) of consolidation pattern and 3/49 patients (6.12%) of crazy paving pattern (Fig. 2).

4. DISCUSSION

Plain X-ray, although less sensitive than chest CT scan, chest radiography is typically the first-line imaging modality used for patients with suspected COVID-19 [10]. For ease of decontamination, use of portable radiography units is preferred [12].

Findings are most extensive about 10-12 days after symptom onset [13]. The radiological features were reported in Hodeidah, Yemen in different patterns namely GGO pattern, consolidation pattern, consolidation with reticulation and bronchiectasis pattern, and crazy paving pattern. Our patterns similar for many studies in different countries, Rodrigues et al and Wong et al described that the most frequent findings are airspace opacities, whether described as consolidation or, less commonly, GGO. The distribution is most often bilateral, peripheral, and lower zone predominant [5,13]. In contrast to parenchymal abnormalities, pleural effusion is rare.

The primary findings on CT scan in adults have been reported as GGO (bilateral, subpleural, peripheral, basal distribution), crazy paving appearance (GGO and inter-/intrapulmonary septal thickening), consolidation, bronchovascular thickening in the lesion, traction bronchiectasis [14 – 20]. Atypical CT scan findings, these findings only seen in a small minority of patients should raise concern for superadded bacterial pneumonia or other diagnoses as mediastinal lymphadenopathy, pleural effusions: may occur as a complication of COVID-19, multiple tiny pulmonary nodules (unlike many other types of viral pneumonia) , tree-in-bud, pneumothorax and cavitation [5, 21,22]. Temporal CT scan changes, four stages on CT scan have been described 1) early/initial stage (0-4 days): normal CT scan or GGO only (up to half of patients have normal CT scan within two days of symptom onset); 2) progressive stage (5-8 days): increased GGO and crazy paving appearance; 3) peak stage (9-13 days): consolidation; and 4) absorption stage (>14 days): with an improvement in the disease course, "fibrous stripes" appear and the abnormalities resolve at one month and beyond [17, 22-24].

GGO was first described by the Fleischner Society. GGO is defined as blurred areas with slightly increased lung density and the absence of shading of the bronchi and edges of blood vessels, which may be attributed to the partial displacement of air resulting from partial air filling or interstitial thickening. GGO in several studies usually appear on 0–5 days after the onset of initial symptoms. Consolidations " Pulmonary consolidation refers to the replacement of alveolar air by pathological fluids, cells, or tissues and manifests an increase in the density of the lung parenchyma, resulting in obscuring the margins of vessels and airway walls. Consolidation usually is observed in the progressive or the peak stage (4–14 days after the onset of the initial symptoms). The crazy-paving pattern is another important CT scan feature, which shows GGO with superimposed interlobular and intralobular septal thickening, akin to irregular paving stones (This sign represents alveolar edema and interstitial inflammatory reaction). The appearance of crazy-paving patterns is frequently observed in CT scan findings during disease progression (5–8 days after the illness) or in severe cases of COVID-19 [3, 25-27].

In Italy, the following alterations were more commonly observed: patients with lung consolidations (57.7%), (62.8%) with GGO, (23.5%) with nodules and (66.6%) with reticular–nodular opacities. Patients with consolidations and GGO coexistent in the same radiography were (35.5%) of total. Peripheral (57.7%) and lower zone distribution (58.5%) were the most common predominance. Moreover, bilateral involvement (69.2%) was most frequent than unilateral one [28]. Other study in China, the predominant pattern of abnormality observed was bilateral (79%), peripheral (54%), ill-defined (81%), and GGO (65%), mainly involving the right lower lobes (27%) of affected segments [29].

Other study in China reported the CT scan images showed pure GGO in 77% and GGO with reticular and/or interlobular septal thickening in 75% patients. GGO with consolidation was present 59%, and pure consolidation was
present in 55% patients. 86% had bilateral lung involvement, while 80% involved the posterior part of the lungs and 86% were peripheral. Patients older than 50 years had more consolidated lung lesions than did those aged 50 years or younger [30]. In addition, in the youngest group of patients (less than 50 year), 79 % had GGO, and only 21 % had lung consolidations. Atypical findings were reported more common in older patients. This result agreed with previous study was reported by Song et al. 77% had GGO, and only 23% had lung consolidations, while in the group of patients over 50 years, GGO were present in 56% and consolidations in 44% and the result similar to a study by Song et al , the incidence of consolidation was significantly higher in older patients (> 50 years) [30,31]. Our finding reported 6.1 % of crazy paving pattern that agreed with study of the Bao et al that had incidence of 14.81% [32].

Finally, in our tertiary center, CT scan examination is usually performed (generally after a chest X-ray) only in specific situations: in case of clinical-radiological discordance (when chest X-ray is negative for infective lung involvement, but there is a high clinical-epidemiological suspect), in case of acute complication (pulmonary embolism or severe respiratory failure) or after intubation before transporting patient to ICU.

Limitations of the study: There are some limitations in this study that needs to be considered. The small samples size in confirmation of cases. The study were limited on severe and critical cases only therefore, the study will include in the future the mild and moderate cases.

5. CONCLUSION

The study concluded that different radiological patterns and features were reported in elderly patients with COVID-19 infection associated with risk factors (comorbidity and coinfection). The radiological techniques have good predictive values on severity and mortality. Also can support the clinicians staff in early detection, early triage, criteria admission, and effective management of COVID-19 infection.
